Abstract

Due to observed interactions between Svalbard reindeer (*Rangifer tarandus platyrhynchus*) and polar bears (*Ursus maritimus*) during field work on Edgeøya, Svalbard, we measured response distances for reindeer from a stalking polar bear and improvised five approaches from a person disguised as a polar bear for comparison with human encounters. The alert, flight initiation and escape distances were 1.6, 2.5 and 2.3 times longer, respectively, when Svalbard reindeer were encountered by a person disguised as a polar bear compared to a person in dark hiking gear. Population increase of polar bears on Svalbard and decrease in sea-ice cover in the Arctic region during summer probably results in more frequent interactions with reindeer on the archipelago. Similar reindeer response behavior from encounters with a polar bear and persons disguised as polar bears indicate a predator-prey relationship between the two species on Edgeøya.

DOI: <http://dx.doi.org/10.1657/1938-4246-44.4.483>

Introduction

The insular Svalbard reindeer (*Rangifer tarandus platyrhynchus* Vrolik, 1829) maintain the northernmost populations of *Rangifer*, inhabiting an environment without large grazing competitors and parasitizing insects. Besides rare polar bear (*Ursus maritimus* Phipps, 1774) predator incidences (Derocher et al., 2000) and few killings of newborn calves by Arctic fox (*Alopex lagopus*) (Tyler, 1986), *Rangifer* predators like wolf (*Canis lupus*), wolverine (*Gulo gulo*), lynx (*Lynx lynx*), brown bear (*Ursus arctos*), or golden eagle (*Aquila chrysaetos*) are absent from the Svalbard reindeer's natural habitat. This situation has prevailed for at least 4000 years (Van der Knaap, 1986; Tyler and Øritsland, 1989). Contrary to *Rangifer* subspecies elsewhere and probably as an adaptation to the absence of predators, Svalbard reindeer live individually or in small groups (Alendal and Byrkjedal, 1976; Alendal et al., 1979), are seasonally sedentary (Tyler and Øritsland, 1989), and do not have the nomadic behavior known from other *Rangifer* subspecies. Gregariousness is commonly recognized as a way to escape predation and in the presence of predators, *Rangifer* subspecies in southern Norway, Russia, and North America group together, frequently counting several thousand individuals (e.g. Bergerud, 1974; Skogland, 1989; Syroechkovskii, 1995).

In a comparative study of vigilance and fright behavior of wild reindeer in southern Norway (Reimers et al., 2012) and Svalbard (Reimers et al., 2011), we found Svalbard reindeer to be less vigilant than mainland wild reindeer, but the differences were surprisingly small. Several studies have documented effects of relaxed selection on antipredator behavior in mammals, but at present show no consistency regarding the speed at which prey-discriminative abilities are lost (Caro, 2005). For example, Byers (1997) noted that antipredator behavior in pronghorns (*Antilocapra americana*), apparently designed to evade capture by extinct

predators, has persisted since the last ice age. In contrast, Berger (1998) uncovered a rapid reduction in predator recognition abilities in North American ungulates isolated from predators for just tens of years. Despite the poor recognition skills of predator-naïve prey, wild animals learn about predators rapidly. Although moose (*Alces alces*) that had been unfamiliar with dangerous predators for as few as 50 to 130 years were highly vulnerable to initial encounters, behavioral adjustment to reduce predation transpired within a single generation (Berger et al., 2001).

Last week of our field work on Edgeøya, Svalbard in July/August 2006 (Reimers et al., 2011, 2012), we witnessed a polar bear stalk a group of four reindeer in our study area on Edgeøya (Fig. 1). Earlier, we had observed polar bears on 5 occasions and recorded fresh polar bear tracks on Grunnlinjesletta, along the river Plura and in the inner part of the valley Plurdalen ca. 13 km from the coastline. In the evening of 4 August, a group of 9 reindeer (2 males, 5 females, and 2 calves) were observed grazing in a small side valley in the inner part of Plurdalen. Two days later, a polar bear was lying on the same grazing spot and reindeer were absent from the area. At this time, we had 50 recordings of reindeer responses towards persons approaching them and decided to improvise and disguised a person in white clothing, including a white mask, to simulate polar bear approaches, hereafter designated “polar bear” or “polar bear disguise” (Fig. 2). Since reindeer on Edgeøya have been protected from human hunting since 1925, we assumed that the reindeer would display stronger behavioral responses from encounters with polar bears compared to humans. If so, we would expect longer response distances when reindeer were approached by a human disguised as a polar bear compared to when reindeer were approached by human dressed in dark clothing.

Study Area

The island Edgeøya (ca. 5150 km²), a nature reserve and part of the Svalbard archipelago (Fig. 1), is characterized by glaciers,

FIGURE 1. The study area: Plurdalen valley, Siegfjället, Burmeisterfjellet, and Grunnlinjesletta on Edgeøya, Svalbard, in July–August in 2006.

wide valleys, plateaus, and coastal plains. In the summer (June–September), reindeer are found in the valleys, coastal plains, and to some extent on the plateaus. Strict environmental regulations prevent tourist activities on the island and hence counteract habituation of reindeer to humans as reported elsewhere in Svalbard (Adventdalen) (Reimers et al., 2011). The present total reindeer summer population in Edgeøya is unknown, but was estimated at 1730 ± 451 (SD) for the period 1969–1996 (Øritsland, 1998). The study area was surveyed, and the number of reindeer was estimated at 181 animals in 2006, down from 227 animals in 1976 (Reimers, 2012).

After the international harvest ban in 1973, the population of polar bears in the Svalbard archipelago has increased and was estimated at approximately 2650 animals, half of which probably reproduce in the Svalbard area (Aars et al., 2009). Edgeøya is an important polar bear denning area (Larsen, 1985).

Material and Methods

FRIGHT AND FLIGHT RESPONSES

Flight initiation distance is the distance at which an animal begins to flee from an approaching predator (Ydenberg and Dill, 1986). Because it is relatively simple to systematically approach animals until they flee, it is an excellent metric with which to quantify an individual's fearfulness in various circumstances and is extensively used (Tarlow and Blumstein, 2007).

Behavioral responses were collected in Plurdalen, Grunnlinjesletta, Siegfjället and Burmeisterfjellet (Fig. 1) under snow-free conditions, during “daylight hours” between 0900 and 2400 in July and August 2006 by a single observer on foot. During 67 encounters, the observer dressed in dark hiking clothing and in 5 encounters in a “polar bear disguise” and moving in a forward leaning amble posture (Fig. 2). The observer measured response distances between the reindeer and the approacher and the resultant

FIGURE 2. Lead author disguised as a polar bear approaching a group of Svalbard reindeer. Limited supplies of white clothing left the back of the observer uncovered. Photos by M. Kardel.

displacement distance by the reindeer after taking flight. All response distances were measured with laser monoculars (Leica Rangemaster 1200 Scan; 1 m accuracy at 1000–1200 m).

We used wildlife response distance terminology and methodology recommended by Taylor and Knight (2003) modified for our study by Reimers et al. (2011):

(1) *Start distance*: the distance between the approacher and the individual reindeer (or the closest animal if we encountered a group) before the start of a disturbance.

(2) *Sight distance*: the distance between the approacher and the closest animal when animals in the group displayed an alerted behavior directed at the approacher.

(3) *Alert distance*: the distance when the reindeer exhibited an increased alert response by grouping together or individuals urinating with one hind leg extended outward at an exaggerated angle, while staring at the approacher.

(4) *Flight initiation distance*: the distance from the approacher to the reindeer when the reindeer initially took flight.

(5) *Escape distance*: the shortest straight-line distance from where the reindeer took flight in response to the approacher to where the reindeer resumed grazing or bedded down.

Upon location of individuals or groups, 6 parameters were recorded: group size; group composition (mixed, yearlings and older of both sexes; males, yearlings and older; female(s) with calf at foot); dominant activity of the group when first sighted (lying

or grazing); wind direction relative to the observer (tail wind or into the wind including crossways to the wind); topography of the surrounding area (level or rugged) and direction of the encounter (downhill, flat, or uphill).

The approacher measured the start distance and used a direct approach method (Reimers et al., 2011): advancing directly towards the animal or estimated center of the group at a constant speed ($\approx 4 \text{ km h}^{-1}$) with three stops ($\leq 6 \text{ s}$) to measure the additional response distances (sight, alert, and flight initiation). The observer continued to approach the animal(s) on all occasions until reaching the position where the reindeer were located at the start of the disturbance for measurement of the escape distance from this point. All measurements were made from the position of the approacher to the closest animal in a group.

STATISTICAL METHODS

Reindeer were probably repeatedly approached during the field period but not on the same day, except the day when a group of 4 reindeer were approached first by a polar bear and again later by a person in “polar bear disguise.”

Start, sight, alert, flight initiation, and escape distances were analyzed with linear models (LM) using statistical software R (<http://www.r-project.org>). Due to strongly imbalanced data, we reduced the encounters made by a person ($N = 67$) to include only mixed groups and individuals or groups of either females or males ($N = 56$), excluding females with calves at foot. Next, we included only fixed effects that were the same as when we approached in disguise (grazing animals, level terrain, head wind, and downhill or level encounters; $N = 11$). The model fixed effects included approacher (person or “polar bear”), start distance in the sight model, and sight distance in the alert and flight initiation models (both centered at their means) (Table 1). To facilitate interpretation of the disturber on the four vigilance measures, we present predicted response values for encounters by person and “polar bear” (Fig. 3), which also show response distances in the total sample excluding females with calves ($N = 56$).

As a measure of effect size for the different treatments (persons vs. “polar bears”), we calculated d-scores (Cohen’s effect size) for the different distances, subtracting the mean of the control group (person) from the mean of the experimental group (“polar bear”) and dividing by the pooled standard deviation (Cohen, 1988).

Results

A person dressed in dark hiking gear approached individuals or small groups of reindeer (≤ 11 ; median = 2) 11 times, and was disguised as a “polar bear” 5 times during July and August 2006 (Appendix Table A1). The response distances for alert, flight initiation, and escape were 1.6 (2.0), 2.5 (3.2), and 2.3 (4.0) times longer, respectively, when Svalbard reindeer were approached by a person in “polar bear disguise” compared to a person in dark hiking gear. (Numbers in parentheses relate to person sample size [$N = 56$]).

Start distance was longer (673 vs. 374 m [median 480 vs. 393 m]) when reindeer were approached by a “polar bear” compared to a person in dark hiking clothing (Table 1). Start distance did not influence sight distance, which did not differ between the two

TABLE 1

Summary of the linear models for predicting start, sight, alert, flight initiation, and escape distances of Svalbard reindeer groups disturbed by an approaching person ($N = 11$) or person disguised as polar bear ($N = 5$) in Edgeøya, Svalbard, in July–August 2006. Reference levels for approacher is person disguised as a polar bear. Fixed effect values for start distance and sight distance were centered around the mean.

Measurement	Estimate	SE	<i>t</i> -value	<i>P</i> -value
Start distance (m) Intercept	673	91	7.36	<0.001
Approacher (person vs. polar bear)	− 299	110	− 2.71	0.017
Sight distance (m) Intercept	254	49	5.14	<0.001
Start distance	0	0	1.31	0.214
Approacher (person vs. polar bear)	− 6	63	− 0.09	0.928
Alert distance (m) Intercept	220	26	8.60	<0.001
Sight distance	0	0	2.54	0.027
Approacher (person vs. polar bear)	− 83	32	− 2.55	0.027
Flight initiation distance (m) Intercept	231	19	12.11	<0.001
Sight distance	0	0	1.27	0.230
Approacher (person vs. polar bear)	− 139	24	− 5.76	<0.001
Escape distance (m) Intercept	366	61	5.96	<0.001
Approacher (person vs. polar bear)	− 210	74	− 2.83	0.013

approaches: 254 m (95% CI: 156 to 352 m) for “polar bears” vs. 248 m (95% CI: 122 to 374 m) for person in dark hiking gear (Figure 3, Table 1). Although not significant, the sight distances appear to be longer when reindeer were approached by a “polar bear” than when approached by a person in dark clothing (see both person samples in Fig. 3). Lack of significance most probably relates to small “polar bear” sample size.

Reindeer became alert at 220 m (95% CI: 168 to 272 m) and initiated flight at 231 m (95% CI: 193 to 269 m) when they were

approached by a “polar bear” compared to 137 m (95% CI: 73 to 201 m) and 92 m (95% CI: 44 to 140 m), respectively, when approached by a person (Fig. 3, Table 1).

Escape distance was 366 m (95% CI: 244 to 488 m) when approached by the “polar bear” and 156 m (95% CI: 8 to 304 m) by a person. The furthest distance for an escape response was 455 m (median = 358 m) when approached by a “polar bear” and 460 m (median = 105 m) by a person.

A *d*-score as a measure of effect size for the different treatments (persons vs. “polar bears”) were: start: 1.22, sight: 0.56, alert: 1.29, flight initiation: 1.76 and escape distance: 1.26, which translates into a median effect for sight distance and a large effect for the other distances (Ellis, 2010).

On one occasion, we observed a polar bear approaching a group of 4 reindeer into the wind from a start position of ca. 1500 m. The reindeer discovered the bear at approximately 400 m, became alert and initiated running/flight simultaneously at ca. 300 m. They slowed down after ca. 350 m and watched the bear at a closest distance of approximately 250 m (equaling an escape distance of ca. 350 m) as the bear had changed direction towards another small group of grazing reindeer. This second group was approached as the polar bear made use of ridges and narrow depressions, apparently undetected by the reindeer. At a point where no further hidden approach was possible, the bear laid down head pointing towards the animals. It remained there when we retreated to base camp after approximately one hour. The bear did not change its slow moving speed during the two approaches.

Discussion

Alert, flight initiation, and escape distances were 1.6, 2.5, and 2.3 times longer, respectively, when Svalbard reindeer were encountered by a person in “polar bear disguise” compared to a

FIGURE 3. Predicted values ($\pm$ SE) of sight, alert, flight initiation, and escape distances of Svalbard reindeer groups disturbed by an approaching person or person disguised as a polar bear ($N = 5$) in Edgeøya, Svalbard, in July–August 2006. Person I denotes 11 encounters where model fixed effects (herd structure, terrain, wind, etc.) were similar to those when reindeer were encountered by a person in polar bear disguise. Person II denotes all person encounters excluding those of females with calf at foot. Polar bear denotes an approach by a single polar bear towards a mixed group of 4 reindeer (three females and one male). Polar bear response distances were estimated from GPS positions and maps.

person in dark hiking gear. It is reasonable to assume that contrasting white color facilitated a longer sight distance than when approaching in dark gear, which is further enhanced in the larger sample ($N = 56$) and less so in the small sample ($N = 11$). Apart from sight distance, the two samples ($N = 11$ and $N = 56$) did not predict the response distances differently although the larger sample tended to give somewhat shorter response distances (Fig. 3). As sight distance was correlated to neither flight initiation nor escape distance (Reimers et al., 2011), it is unlikely that visibility (white color vs. dark clothing) in itself should cause the longer fright and flight responses for the “polar bear” encounters unless the reindeer associated the appearance of the approaching white object with a threat, i.e. a predator. Even if our sample size is small, our results support an experience-dependant escape response that is adjusted to the level of potential predation risk, and not a response to a difference in visibility of the approaching object.

The way in which a population’s anti-predator behavior is modified depends on its underlying developmental mechanisms in terms of both heritable predisposition (Riechert and Hedrick, 1990) as well as experience (Berger et al., 2001; Blumstein, 2004). Deecke et al (2002) found that harbor seals (*Phoca vitulina*) are capable of complex discrimination of different stimuli and that they may modify their predator image by selectively habituating only to harmless stimuli. They concluded that fear in seals is focused on local threats by learning and experience. The predator recognition may be olfactory, acoustic, and visual (Blumstein et al., 2000; Deecke et al., 2002; Webb et al., 2010; Kappel et al., 2011). Since there were no olfactory or acoustic stimuli in our study (head wind and no noise from the observer apart from normal walking noise during all approaches), predator recognition must have been associated with the visual image of the encountering object. Deecke et al (2002) observations are relevant in this context. They found that seals responded strongly towards both meat-eating killer whales and unfamiliar fish-eating killer whales, but not to local familiar fish-eating killer whales.

Although one observation of a polar bear approach ($N = 1$) provides little supporting evidence, it does not contradict the “polar bear disguise” response distances. This one encounter indicates that Svalbard reindeer indeed perceive polar bears as a predator. This is supported by Derocher et al. (2000) who in 1983–1999 (March–April) collected observations of seven predation events and six instances of scavenging of Svalbard reindeer by polar bears. Furthermore, in two recent newspaper articles, Hovelsrud (2009) and Sandal (2008) reported the killing of two reindeer males by polar bears in late spring (1991) and September (2008). Both males were apparently killed as a result of an ambush attack or a successful stalk. Also, Brook and Richardson (2002) reported that a polar bear was observed stalking and chasing caribou in western Hudson Bay in July. Even if these incidences are rare events, they show that polar bear may predate reindeer in all seasons, and thus lend support to a predator-prey relationship between the two species.

Experience-dependant behavior may be lost after the first generation in the absence of predators, while more “hard-wired” antipredator behavior may persist for thousands of years following isolation from predators (Byers, 1997; Coss, 1999). On the other hand, experience-dependant behavior may be quickly restored the

first time individuals encounter predators (Brown et al., 1997). In accordance with this, we found a 2.2 times higher vigilance rate displayed by reindeer in Edgeøya with a dense polar bear population compared to reindeer in Nordenskiöld Land with fewer polar bears (Reimers et al., 2011). However, Svalbard reindeer maintain small group size (average and median 2.9 and 2 animals, respectively) both on Edgeøya and in Nordenskiöld Land (Reimers et al. 2011). Maintenance of small group size is not expected if reindeer were exposed to strong predation pressure (see review by Caro, 2005, Table 4.4).

According to a recent summary report from the IUCN Polar Bear Specialist Group, there was likely an increase in the Barents Sea polar bear subpopulation from 1973 until recently (IUCN, 2010). Also, the sea-ice cover in the arctic region during summer has decreased (Singarayer et al., 2006) and is expected to continue decreasing in the years to come (Zhang and Walsh, 2006). This has caused an increase, and will probably continue influencing an increase in the amount of time individual polar bears spend on land (Derocher et al., 2004; Schliebe et al., 2008; Gleason and Rode, 2009). As a result, polar bears and reindeer are together for longer periods, a situation in which interactions between them could occur more frequently (Derocher et al., 2000). Nevertheless, we do not anticipate short-term effects on reindeer other than temporary and local changes in distribution and behavior (Reimers, 2012). The possibility for behavioral changes of both reindeer and polar bears in response to future increased interactions calls for a follow up study.

Acknowledgments

We thank the Governor on Svalbard for the necessary landing allowances on Edgeøya, The Norwegian Polar Institute for rent of necessary field equipment, M. Kardel and K. Reimers Kardel for field assistance, D. T. Alemu for statistical support, T. Severinsen for technical support, and J. E. Colman for linguistic support. Financial support was provided from The Norwegian Science Foundation, The Norwegian Polar Institute, and Framkomiteens Polarfond. A special thank to C. Bonenfant, V. B. Meyer-Rochow, S. C. Amstrup, and D. T. Blumstein for their constructive criticism of a previous version of the manuscript.
