Garty, G., Xu, Y., Elliston, C., Marino, S. A., Randers-Pehrson, G. and Brenner, D. J. Mice and the A-Bomb: Irradiation Systems for Realistic Exposure Scenarios. *Radiat Res.* 187, 475–485 (2017).

Validation of biodosimetry assays is normally performed with acute exposures to uniform external photon fields. Realistically, exposure to a radiological dispersal device or reactor leak will include exposure to low dose rates and likely exposure to ingested radionuclides. An improvised nuclear device will likely include a significant neutron component in addition to a mixture of high- and low-dose-rate photons and ingested radionuclides. We present here several novel irradiation systems developed at the Center for High Throughput Minimally Invasive Radiation Biodosimetry to provide more realistic exposures for testing of novel biodosimetric assays. These irradiators provide a wide range of dose rates (from Gy/s to Gy/week) as well as mixed neutron/photon fields mimicking an improvised nuclear device. © 2017 by Radiation Research Society

INTRODUCTION

The radiation fields normally encountered in radiation protection scenarios are typically complex involving a wide range of dose rates and radiation qualities. Realistically, exposure to a radiological dispersal device (RDD) or reactor leak will include exposure to low-dose rates and likely exposure to ingested radionuclides. An improvised nuclear device (IND) will likely include a significant neutron component in addition to a mixture of high- and low-dose-rate photons and ingested radionuclides.

To effectively respond to these scenarios the U.S. Government is supporting development of medical coun-

termeasures against radiation as well as high-throughput biodosimetry which can be used for identifying exposed individuals who would benefit from them (1). This requires testing of countermeasures and biodosimetry using irradiation fields that mimic realistic exposure scenarios that include neutron exposures, a wide range of dose rates and internal emitters. Despite this, validation of biodosimetry assays is normally performed with acute exposures to uniform external photon fields.

The Radiological Research Accelerator Facility at Columbia University has been developing novel irradiation systems and radiation measuring devices for 50 years. In this article, we describe the irradiation systems developed for modeling realistic radiation exposure scenarios within the context of radiation biodosimetry and discuss their use.

SCENARIOS

Over the past decades, with changes in technology and global politics, the planning scenarios for radiological events (Fig. 1) have shifted: Through the late 1980s planning revolved around a major exchange of sophisticated nuclear devices between the two superpowers (2, 3). During the 1950s and 1960s it was believed that sheltering in place could provide adequate protection to the population (2). Later planning scenarios (3) assumed that most of the population near potential detonation sites, could be evacuated and sheltered in the days leading up to the attack. This scenario specifically states that “attention should not be given to protection against nuclear blast and fire” near the detonation sites as it would not be feasible to do so. The post attack planning (3, 4) thus concentrated on protecting the evacuees from fallout (by sheltering), surveying fallout levels and transporting food and fuel to the evacuees. It was assumed that all exposures would be “intentional” (i.e. leaving the shelter for some important reason) and accompanied by physical dosimetry.

These approaches were criticized by the medical community as unrealistic (5, 6), stating that the destruction and loss of life (especially within the medical professions) was likely to be much higher than planned and would not

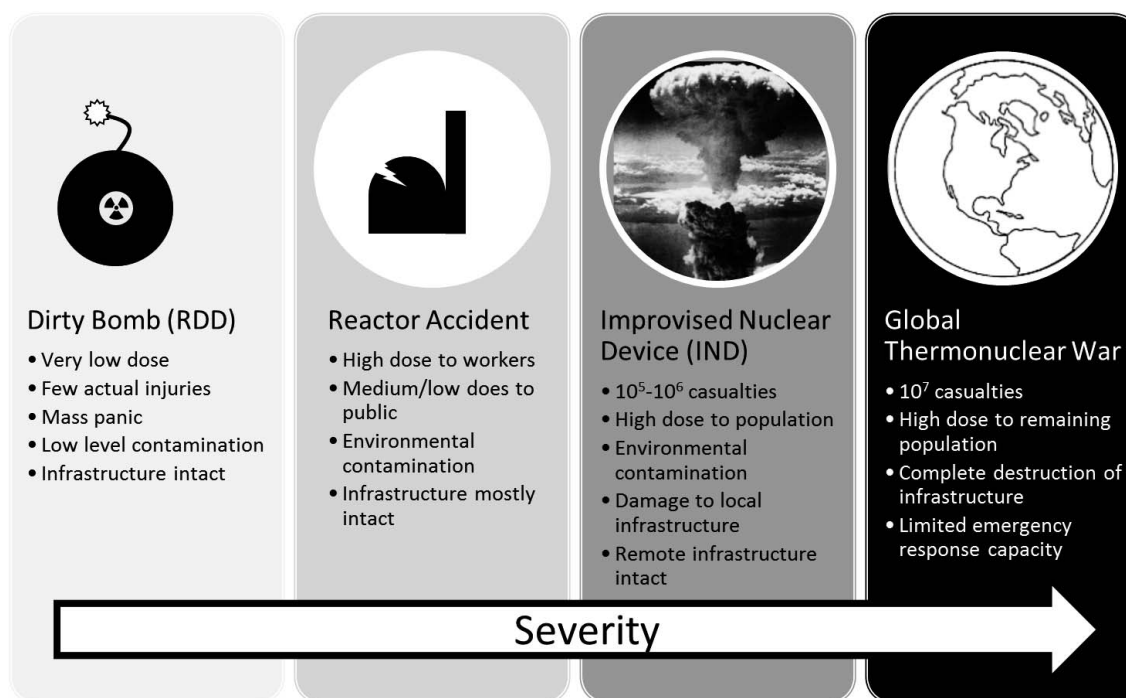

FIG. 1. Scenarios involving radiation exposure to the general population.

allow any type of medical response for treating injured individuals, who were largely ignored in the planning.

With the collapse of the Soviet Bloc, emphasis has shifted dramatically. Recent planning scenarios (7) discuss more limited events for which biodosimetry, triage and medical countermeasures are relevant and therefore are in the planning stages (1).

Improvised Nuclear Device

The main planning scenario being considered [scenario 1 in ref. (7)] involves a single “improvised” device deployed by a terrorist organization. The standard model of such an IND is a 10kT “gun-type” device based on enriched uranium and detonated at ground level, similar to, but somewhat smaller than the Hiroshima bomb, “Little Boy”. This is considered to be the simplest design, based on the most “easily” obtainable nuclear materials.

A notable difference between this IND scenario and the Hiroshima bomb is that an IND is expected to be detonated at ground level, whereas Little Boy was detonated at an altitude of 600 m. The main consequence of this is that buildings will partially shield the photon component but have little effect on the neutron component (8), so that, while total doses would be roughly a third of those at Hiroshima, at the same distance from Ground Zero, the fractional neutron dose, would be significantly higher (9), with a corresponding increase in biological effects.

This type of scenario would therefore consist of the following radiation fields:

- Prompt radiation: a mixture of photons and MeV-range neutrons, delivered essentially instantaneously;
- Delayed radiation: both due to groundshine and fallout. Here significant doses are delivered over a period of days, until the individual is evacuated; and
- Internal emitters: Ingested radionuclides will likely persist in the host for weeks, providing a low level internal irradiation. For example the biological half-life of Cesium-137 in humans is about 100 days (10), unless chelating agents are used.⁴

Significance of Neutrons

Within an IND scenario, a significant fraction of the prompt dose is delivered in the form of MeV-range neutrons. The radiobiological consequences of these neutrons have been studied since the 1960s and they have been shown to be much more effective in the induction of radiation endpoints than photons [e.g. (12)]. Based on Monte Carlo calculations of radiation transport in an urban environment (9), it is expected that the neutron dose at a survivable distance from an IND detonation, would be on the order of 10–20% of the total dose. Factoring in that these neutrons are 2–6 times more effective than photons in inducing cytogenetic damage (8, 13, 14), roughly half of the biological effect observed will be due to neutrons with the other half due to photons. Hence it is important to assess whether the two radiation types act independently or

⁴ For example, Prussian Blue reduces the biological half-life of ¹³⁷Cs to 30–50 days (11).

synergistically in terms of biodosimetric dose reconstruction and in evaluating acute radiation effects. To establish this, it is crucial that biodosimetry assay validation be performed in radiation fields containing a mix of photons and MeV-neutrons.

Significance of Dose Rate

For sparsely ionizing radiation (photons), dose rate is one of the principle factors determining the biological consequences of radiation. For example, below about 1.5 Gy/h, the characteristic time between photon traversals in a cell is longer than the typical time for rejoining (or mis-rejoining) of DNA double-strand breaks (15). Thus at very low-dose rates, sublethal damage is repaired as fast as it is formed. Conversely, at higher dose rates, there is an increased possibility of multiple reparable lesions interacting to form a complex, irreparable lesion. This would indicate that radiation effects from fallout-type exposures, where the dose is delivered over days and weeks would be qualitatively and quantitatively different from similar exposures delivered in minutes. Furthermore, direct experiments (16), and recent measurements of fast repair times for double strand breaks (17) strongly suggest that there will be increased effects from a dose delivered in ~ 1 s, compared with the same dose delivered in ~ 1 min. Nevertheless, the bulk of exposures used in biodosimetry and countermeasure testing utilize dose rates of about 1 Gy/min.

Other Radiological Devices

Radiological Dispersal or Exposure Devices (RDD/RED) are easier to construct than an IND. In an RDD, a quantity of radioactive material is mixed with explosive and detonated, thus the radioactive material is aerosolized and dispersed in the environment. Typical scenarios talk of such a device made from ^{137}Cs , ^{60}Co , ^{90}Sr or ^{241}Am , which are all used industrially and are potentially available in significant quantities. An RED is essentially the same thing but without the explosive – a large gamma emitter is placed in a public location with the hopes of exposing as many people as possible.

In either case the public health consequences are small. While there would probably be mass panic, there would be very few individuals who would actually require medical intervention. A good model for this scenario is the Goiânia accident (18), where a 1375 Ci ^{137}Cs teletherapy source was accidentally dispersed. In a city of 1 million people, 249 individuals were contaminated (of them 151 contaminated internally), 49 individuals required hospitalization, 28 suffered radiation burns and five died (8).

It is therefore likely that an RDD/RED would result in a few hundreds or thousands of individuals contaminated (internally or externally), receiving low-dose-rate irradiations over a period of days to weeks with a much smaller number of acutely irradiated individuals (who will likely also be injured by the blast). In the specific case of an RDD based on an alpha emitter (e.g. ^{241}Am or ^{210}Po), identifying

internally exposed individuals without using a biological assay is near impossible due to the short range of the alpha particles, on the other hand, these individuals are those who would need treatment most, as even a low dose of high-LET alpha particles would have significant biological consequences.

Radiological Accident

Presently, more than 400 nuclear power plants are in use globally (19). These reactors are in risk of accidental release of radiation due to human error [as in the case of Chernobyl (20) or Three Mile Island] or natural disaster (as occurred at Fukushima). In such a scenario, the affected individuals can be divided into two groups, radiation workers and general population. The radiation workers include individuals within the plant during the disaster as well as the cleanup workers and are potentially exposed to high doses of radiation. These individuals typically would have physical dosimetry and would not necessarily require bioassays for triage. The general population, however, would likely be exposed to low-dose rates of radiation, either externally or via radionuclides (in particular ^{137}Cs , ^{134}Cs , ^{90}Sr and ^{131}I) entering the food chain (21, 22) and would potentially require the use of bioassays.

What arises from these scenarios is the need for both triage and countermeasures in mixed irradiation scenarios that may contain a mixture of neutrons and photons and/or a broad range of exposure timescales, from fractions of a second to days and weeks. It is therefore critical to have available irradiators that can provide such irradiation fields in a controlled, reproducible manner. At the Radiological Research Accelerator Facility, we have developed (and are continuing to develop) several such facilities, allowing both *ex-vivo* irradiation of blood samples and *in vivo* irradiation of small animals.

Model Systems

With the exception of patients undergoing therapeutic irradiation (23, 24) and the rare accidental exposure (25), it is not feasible to validate biological dosimetry assays in *in vivo* irradiated humans. To perform these studies under controlled irradiation conditions, one is therefore limited to irradiation of animal model systems or blood from “healthy” human volunteers. While the latter is extremely useful for testing blood-based biodosimetry assays, one or more animal models are required for testing and FDA approval of both biodosimetry devices and medical countermeasures (26).

The bulk of *in vivo* studies in biodosimetry and medical countermeasure development are performed in mice. A wide variety of mice strains, with varying degrees of radiation sensitivity (27, 28), are commercially available and can be used for exploratory studies. Once an appropriate candidate drug or biomarker is identified, it

FIG. 2. Comparison of a pure fission spectrum (solid line) and the spectrum from “Little Boy”. Data reproduced from ref. (40).

can be further validated in non-human primate (NHP) experiments which are significantly more expensive and complicated to perform.

Due to the larger size of NHPs, they require significantly larger radiation fields, and more penetrating radiations – while mice studies can be easily performed with X rays from a standard orthovoltage machine operating at 250–320 kVp, NHP studies are better performed with more penetrating gamma rays from a ^{137}Cs - or ^{60}Co -based irradiator and even then are typically performed by either irradiating the animal twice (front and back), or rotating the animal during irradiation, to achieve a homogenous exposure.

The irradiation systems described below are aimed at initial stage studies, using *ex vivo* irradiated human blood and *in vivo* irradiated mice.

IRRADIATION FACILITIES

Neutrons

Two types of neutron irradiation systems are generally available for radiobiology studies, reactor based and accelerator based.

In a reactor based system [e.g. (29–31)], neutrons are generated via ^{235}U fission, with a wide range of energies peaked around about 1 MeV. Depending on the type of reactor used, unmoderated fission neutrons can be obtained directly (32) or by using a ^{235}U converter to transform thermal neutrons from a small research reactor to fission neutrons (29). Samples can be either inserted into the reactor core or exposed to neutrons extracted via a window into an experimental room. The latter allows exposing large specimens, such as NHP.

For example, the Petten reactor (29), used for key *in vivo* neutron RBE studies (for hematopoietic and GI death) (33, 34), is a small research reactor using a standard ^{235}U fuel

plate as a converter resulting in a highly uniform flux of energetic neutrons allowing irradiation of mice or NHP at a dose rate of up to 6 Gy/h.

Accelerator based systems use ion beams, typically protons or deuterons, impinging on a low-Z target (for example beryllium or tritium-impregnated titanium). Neutrons are formed via nuclear reactions with different energy neutrons emitted at different angles with respect to the beam direction. In this case, by adjusting the beam type and energy, target type and angle to the sample, quasi-monoenergetic neutron beams (energy spread of up to $\pm 15\%$) can be generated. Due to the angular dependence of the neutron energies, such a facility is limited to irradiation of small samples, which subtend an angle of about 10° , as seen from the target. Larger samples will suffer increased inhomogeneity in both neutron energy and flux.

For example, the neutron facility at the Radiological Research Accelerator Facility (RARAF)⁵ has had 50 years of experience performing neutron irradiations of small animals (35, 36) and of cells (37–39) using monoenergetic neutrons having energies from 0.22 to 15 MeV (12).

IND-Spectrum Neutron Irradiator

However, neither monoenergetic nor fission spectra are appropriate for studying IND-type exposures. While the initial neutrons with a fission spectrum are formed in the bomb, the spectrum changes dramatically as the neutrons are transported through the bomb casing and a kilometer or more of air. For example, Fig. 2 contrasts the bare fission spectrum and the Hiroshima source term (40). As can be seen the bare fission spectrum is much harder than the one from an actual bomb.

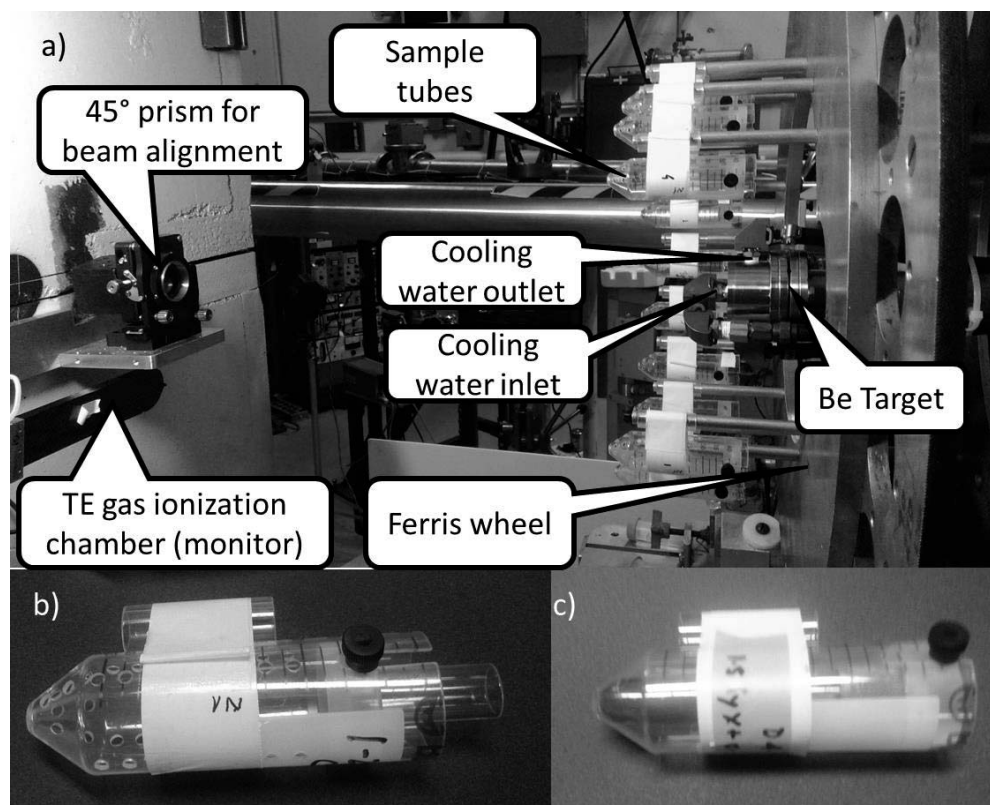

FIG. 3. Panel a: The neutron irradiation facility [Reproduced with permission from (13)]. Panel b: Sample tube for irradiating mice. Panel c: Sample tube, containing human blood for *ex vivo* irradiations.

For generating neutron fields, mimicking exposure from an IND, we have developed an accelerator based neutron source [Fig 3a, (13)], providing neutrons having the same energy spectrum as those modeled for Hiroshima (41, 42) at 1 km from the epicenter [where we would expect a survivable neutron dose of about 0.25 Gy (9)]. The facility is designed for performing irradiations of mice (unpublished data) and of blood (13).

Briefly, samples are placed in modified 50 ml conical tubes (Fig. 3b and c) placed on a Ferris wheel, rotating at 30 revolutions per hour around the beryllium target. A mixed beam of roughly 15% protons, 30% deuterons and 55% molecular ions is accelerated to 5 MeV and bombarded on a thick beryllium target generating a spectrum of neutrons with a dose rate of 0.085 [Gy/h/ μ A of beam], at the sample location, with an additional 17% photon dose, delivered simultaneously. In order to allow measuring other photon/neutron mixes, a highly filtered 250kVp X-ray machine is available.

Results

Using this source, we have tested a variety of cytogenetic and transcriptomic endpoints:

For micronuclei, for example, we have seen that these neutrons are roughly 4 times more efficient than photons (13) and have preliminary data demonstrating that, micronucleus formation by neutrons and photons is

additive. We are also investigating dicentrics and inter-chromosome translocations (43) as possible biomarkers. The latter is known to be much more sensitive to densely ionizing radiation (such as neutrons). Reconstruction of the fraction of dose due to neutrons vs. photons would therefore be possible when using this a translocation assay in conjunction with a second assay such as dicentrics or micronuclei.

In parallel transcriptomic studies (unpublished data), we have identified genes that are sensitive to radiation quality as well as genes that were insensitive to it. This will allow developing transcriptomic signatures that can identify both the total dose received and the fraction of neutrons.

Furthermore, metabolomic and lipidomic analyses of easily accessible biofluids from mice irradiated using these neutrons have shown a distinct dysregulation of metabolism as well as alterations of basic metabolic functions such as energy metabolism through fatty acid beta oxidation.

High-Dose-Rate Irradiator

Standard X-ray irradiators typically provide dose rates of about 1 Gy/min. This can be somewhat increased by reducing filtering and placing samples close to the X-ray tube, but in such a case, beam quality (spectrum and beam homogeneity) may suffer. Industrial gamma irradiators, providing high dose rates on the order of multiple Gy per second are available but they typically have a high minimal dose, due to the time required to insert/retract the sample

FIG. 4. Low-dose-rate irradiation chamber for (panel a) blood and (panel b) mice.

into the irradiator, and thus do not allow irradiations to doses relevant for biodosimetry. Medical linear accelerators, on the other hand, provide both high dose rates and very low minimal delivered dose. Both are required for rapid and efficient stereotactic radiosurgery or IMRT, where the prescribed dose is split into hundreds of radiation pulses delivered from different directions and using differing collimation patterns (44).

The prevalence of these devices [over 11,000 deployed worldwide (45)] makes them an ideal candidate for use in radiobiology studies. We are currently investigating the use of one such device (the Varian TruBeam) for performing high-dose-rate whole-body irradiation of mice and blood. Preliminary measurements using the TrueBeam available at Columbia University Medical Center demonstrated that dose rates of 2 Gy/s over a 6×6 cm area are easily achievable using the machine in its standard configuration. A dose rate of about 5 Gy/s, would be attainable with the flattening filter removed. While this does not yet match the dose rate from an IND, which would be on the order of Gy/ μ s, it does allow irradiations which would be instantaneous on the time scale of biological DNA damage processing.

Low-Dose-Rate Irradiations

For performing studies of dose rate effects in the range of Gy/min to Gy/day, a standard X-ray machine may be used. At our facility, we have modified an X-Rad 320 (Precision

X Ray Inc., North Branford, CT) to support long term irradiations of mice and blood (46, 47). An important requirement in beam preparation is that the radiation quality be the same in both high-dose-rate (HDR) and low-dose-rate (LDR) modes. This is typically not the case when using shielding to reduce dose rate as the added shielding may filter the X Rays to some extent. We therefore designed a custom Thoreaus filter (1.25 mm tin, 0.25 mm copper, 1.5 mm aluminum HVL: 4.9 mm copper) to allow a wider range of dose rates than that available with the standard filters provided with the X-Rad. Using this filter, we were able to provide 4 Gy/day at a source to surface distance (SSD) of 90 cm and 0.1 mA and 1 Gy/min at 40 cm SSD and 12.5 mA, with a variation of about $\pm 6\%$ across a 25×25 cm field.

Ex Vivo Irradiations

For *ex vivo* irradiations, low-dose-rate experiments require storage of blood samples for many hours under controlled environmental conditions, mimicking those found in an incubator (37°C, 5% CO₂, 80% humidity). To fulfill this requirement, we built a custom incubator (47–49) (Fig. 4a) mainly made of plastic to minimize scattered radiation. Temperature is controlled through solid-state heaters on a feedback loop attached to the walls of the incubator to distribute the heat evenly. The CO₂ concentration, humidity and temperature within the incubator were

FIG. 5. Biokinetics of cesium in mouse and man. The full circles represent the time dependent dose rate from ingested ^{137}Cs , as per the model described in (10). Open circles are from our own data based on total body counting in mice (49).

monitored using data loggers. Blood is exposed in 50 ml conical tubes angled to increase surface area and therefore gas exchange and to keep the samples within a 20 cm diameter and minimize planar dose variation. The tube holder is rotated at three rotations per hour to further minimize any dose inhomogeneity.

Tests have shown that the temperature within our custom incubator fluctuates approximately $0.5\text{--}1.5^\circ\text{C}$, over a 24 h time period, somewhat higher than that in a commercial incubator. We, therefore investigated whether this temperature variation was likely to confound assays of radiation response by measuring expression of two heat shock (HSPA1L and HSPH1) and 1 cold shock (CIRBP) genes using quantitative real-time RT-PCR. With the temperature maintained at a nominal 37°C , there was no difference in gene expression between our custom incubator and a commercial one.

In Vivo Irradiations

For *in vivo* irradiations of mice, the situation is different, as mice need to be maintained at lower temperatures than those achieved within an enclosed X-ray machine operated continuously for 24 h. We have designed and constructed a “mouse air conditioner” consisting of a CPU cooling fan, a water pump with cooling element and an ice bath. The CPU cooling fan is a double fan with a radiator between the two fans. Cold water circulates through the radiator, cooling the blown air. Measurements show that this design adequately cools both the inside of the irradiator and the inside of the mouse housing maintaining a temperature of $22 \pm 0.5^\circ\text{C}$.

In addition to temperature control, mice require a 12 h day/night cycle and adequate space. When irradiating mice using X rays, it is important that the mice are not able to

huddle, and shield each other from radiation (this is less of an issue using a ^{137}Cs irradiator, which has more penetrating radiation). We have therefore built custom mouse housing (Fig. 4b) that can hold up to 8 mice, in individual compartments $[6\text{ cm (w)} \times 12.5\text{ cm (l)} \times 12\text{ cm (h)}]$. Each compartment was supplied with food, bedding and water (via an all-plastic water bottle). Ten air volume changes are provided per hour, satisfying animal care requirements.

Results

Using this low-dose-rate irradiator we have studied a variety of cytogenetic (46, 47), transcriptomic (48, 50) and metabolomic (49) endpoints. We have seen that both HDR and LDR perturb the same general metabolic pathways but that individual metabolites may be used to discriminate between high- and low-dose rates (49). Similarly gene expression patterns in both mouse (50) and *ex vivo* irradiated blood (48) showed gene signatures that were independent of dose rate as well as signatures that were dose rate dependent. As expected, micronuclei (47) showed a linear dose response for LDR and a quadratic dose response for HDR, indicating repair of sublethal damage in the former.

Ultra-Low-Dose Rate

It is likely that ^{137}Cs is the most biologically important fission product from many IND (51), RDD (7) or nuclear accident (52) scenario. Thus, further research regarding the effects of ^{137}Cs , both from internal or external exposure, is much needed (53). To model this in animal studies, we and others have previously used an injection of soluble $^{137}\text{CsCl}$ (54–56). In these studies, the amount of activity of the solution can be varied to produce a specific absorbed cumulative dose by specific time points with the time dependence of the dose determined by the biokinetics of Cs within the animal under study (Fig. 5). This type of experiment is complicated to do – resulting in radioactive excreta and biofluids, which require dedicated “hot” equipment for analysis and, secondly, disposal is expensive.

An alternate approach is to use a low-dose-rate, external ^{137}Cs source that can be adjusted to provide a variable dose rate. Due to the high energy of the ^{137}Cs gamma rays, the physical dose distribution will be the same for the internal vs. external exposures.

The advantages of such a system are clear: it allows for simpler experiments and moreover decouples the time dependence of the dose delivered from the biokinetics in the animal model used. This allows exposing mouse models to the temporal dose profile that would be experience by a human that experiences a different biokinetics (e.g., Fig. 5) or even to a constant ultra-low dose rate.

It should be noted that modeling internal irradiations with external ones is only valid for deeply penetrating ionizations such as ^{137}Cs gamma rays. In order to study the effects of (and develop bioassays for) internal exposure to alpha

FIG. 6. Ultra-low-dose-rate irradiation system under construction.

particles, for example from an ^{241}Am RDD, an injection or inhalation based study is the only valid course of action.

Attenuated ^{137}Cs Irradiator

The Howell group have demonstrated the validity of this approach using a cabinet type ^{137}Cs irradiator coupled to a computer controlled mercury attenuator (57, 58). In their system a mercury reservoir is placed between an 18 Ci ^{137}Cs source and one or more cages holding four mice each. The amount of mercury in the reservoir can be modified attenuating the gamma-ray flux achieving dose rates between approximately 10^{-4} and 0.25 Gy/h (57). This setup has been routinely used for calibration studies for internal emitter biomarker studies (59–61).

Variable Dose-Rate External Irradiator (VADER)

The system under development at our center uses continuously retracting “recycled” low-activity ^{137}Cs brachytherapy seeds. These seeds were much used starting in the 1980s to treat cervical cancer at low dose rate (62), but are no longer in use and many of these ^{137}Cs seeds are in long-term storage, making them readily available. For example, at Columbia University we have available 30 such sources, each in the ~ 20 mCi range.

The design of the system is shown in Fig. 6a: A plastic cage (Fig. 6b), holding up to 18 mice, is placed between two

source assemblies each containing ten 20 mCi ^{137}Cs seeds positioned in a circular pattern, one above and one below the mouse cage. This configuration can provide a dose rate of between 0.05 and 1.5 Gy/day depending on the vertical position of the sources.

During irradiation, the source assemblies (Fig. 6c) are slowly retracted under computer control away from the mouse cage. As the sources are retracted over time-scales of days to weeks, the mice are exposed to a decreasing dose rate that can mimic the dose-rate/time pattern shown in Fig. 5, or any other desired dose-rate/time pattern, such as the much slower ^{137}Cs retention kinetics in man (10), or a constant low dose rate.

For these long-term irradiations the mice are free to move around, eat and drink *ad libitum*. Within the irradiator, temperature, humidity, air flow and lighting are fully controlled to the required animal care standards. Mouse handling is possible at any time by retracting the sources, inserting retractable lead shields (Fig. 6a), opening the interlocked lead cage access door, and extracting the cage.

The VADER device and shielding were designed based on a Monte Carlo transport simulation of the entire system, allowing a design with a predicted spatially uniform dose distribution across the mouse cage, at source-cage separations of 10 cm and greater. Spatial dose homogeneity at the location of the mouse cage will be verified using Gafchromic film, with absolute dosimetry based on a

NIST-traceable ion chamber. Our calculations have also shown that possible dose variations due to mutual shielding (e.g. by mice huddling) are small. Nevertheless we will also verify individual dosimetry on a mouse-by-mouse basis by subcutaneously injecting into each an encapsulated high-sensitivity “pin-worm” LiF:Mg,Cu,P miniature TLD rod. These TLDs (diameter 0.6 mm, length 6 mm,) are designed for insertion into needles/catheters for *in vivo* application and provide a linear dose response up to 10 Gy, and better than 2% reproducibility. Following sacrifice, the TLD will be removed and read, giving the cumulative skin dose received by that mouse.

CONCLUSION

Within a realistic exposure scenario, such as the ones used for national planning purposes (7) it is expected that the population will be exposed to a wider range of dose rates and possibly mixed neutron/photon fields. Nevertheless, the bulk of studies on radiation biodosimetry and radiation mitigators focus on acute doses of photons. Over the past years we have developed several irradiation facilities allowing systematic studies of low dose rates and of mixed neutron/photon exposures using both *ex vivo* irradiated blood and mouse models. These systems have been used for testing various biological endpoints and are also available for mitigator studies in mice. We are currently working on expanding the palette of irradiation systems available to provide a much wider range of dose rates more suited to modeling exposures from the prompt and protracted exposure expected from a nuclear detonation and for modelling the dose profile from ingested ^{137}Cs .
